

Nuclear Astrophysics: a Stellar Spectroscopist's View

Chris Sneden

**Department of Astronomy & McDonald Observatory
University of Texas, Austin**

Galactic Definitions

- Disk populations: thin disk, thick disk, [old disk], bulge
- halo populations: inner, outer, accreted, dissipated
- kinematic versus chemical composition separations
- sub-populations from abundance peculiarities

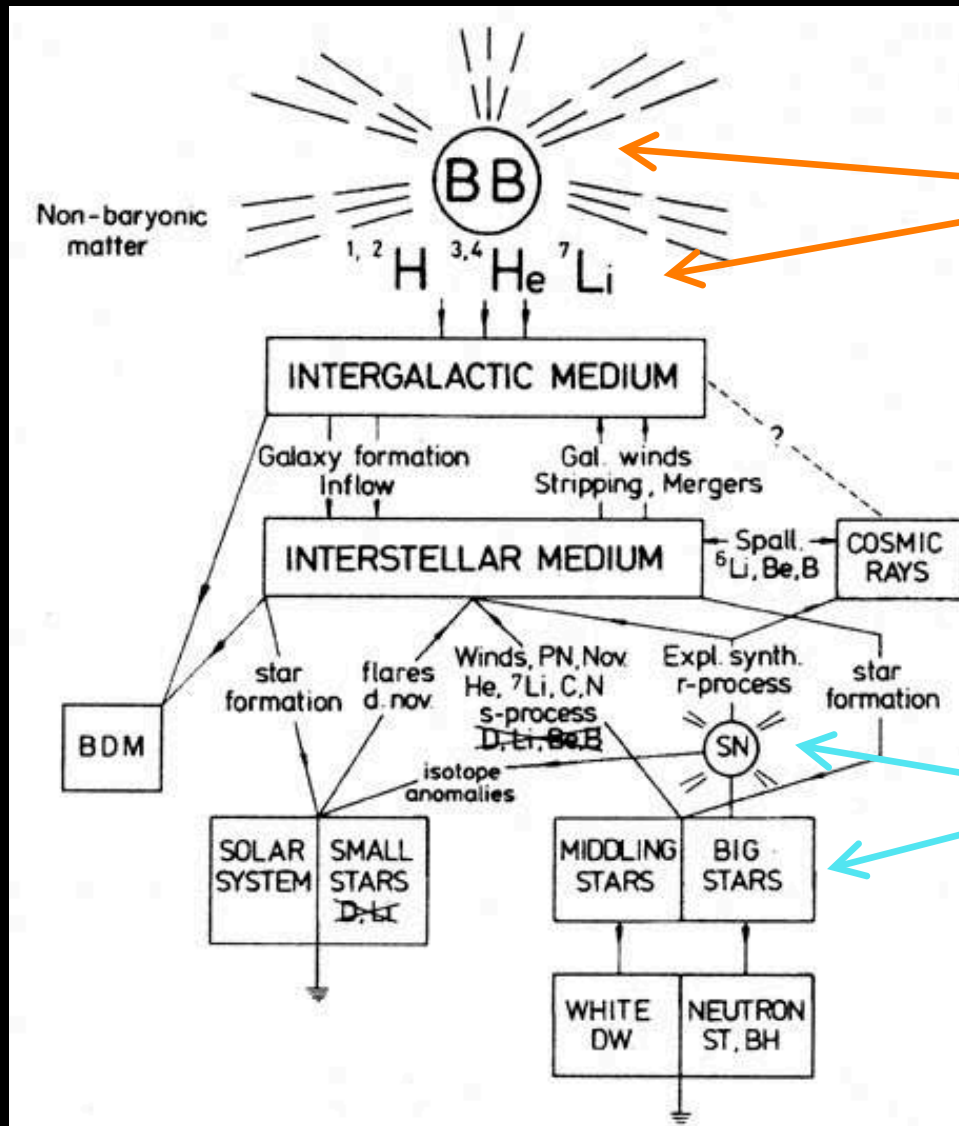

Abundance Definitions

- $\log \epsilon(X) = \log_{10}(N_X/N_H) + 12$ for element “X”
- $[X/Y] = \log_{10}(N_X/N_Y)_\star - \log_{10}(N_X/N_Y)_\odot$
- metallicity: the [Fe/H] value by common usage; all my stars are very metal-poor, or $[\text{Fe}/\text{H}] < -2$
- adjectives of various utility:
 - metal-poor: $[\text{Fe}/\text{H}] < -0.5$ or < -1.0 maybe,
 - very metal-poor: $[\text{Fe}/\text{H}] < -2$
 - extremely metal-poor: $[\text{Fe}/\text{H}] < -3$
 - these are mostly qualitative descriptions

detailed spectroscopy of halo stars reveals 1st Galactic element creation events

Why I will concentrate on metal-poor halo stars

this begins the entire show

all these things come into play to produce the solar system chemical composition

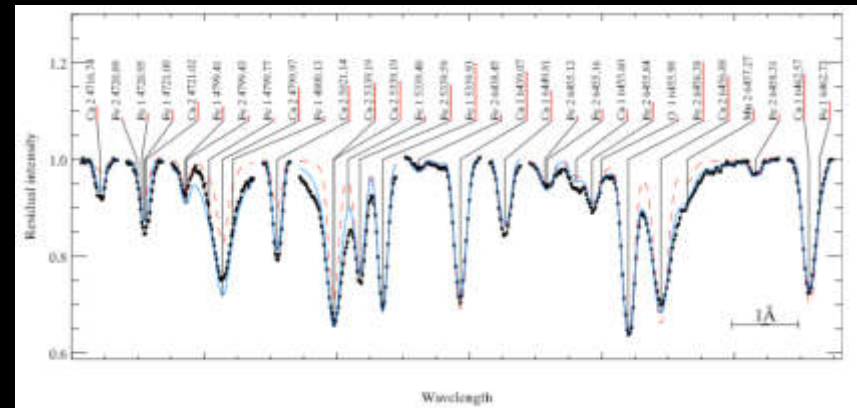

at very low metallicity the scenario is MUCH simpler

exceptions will be noted as needed (e.g., some neutron-capture rich stars)

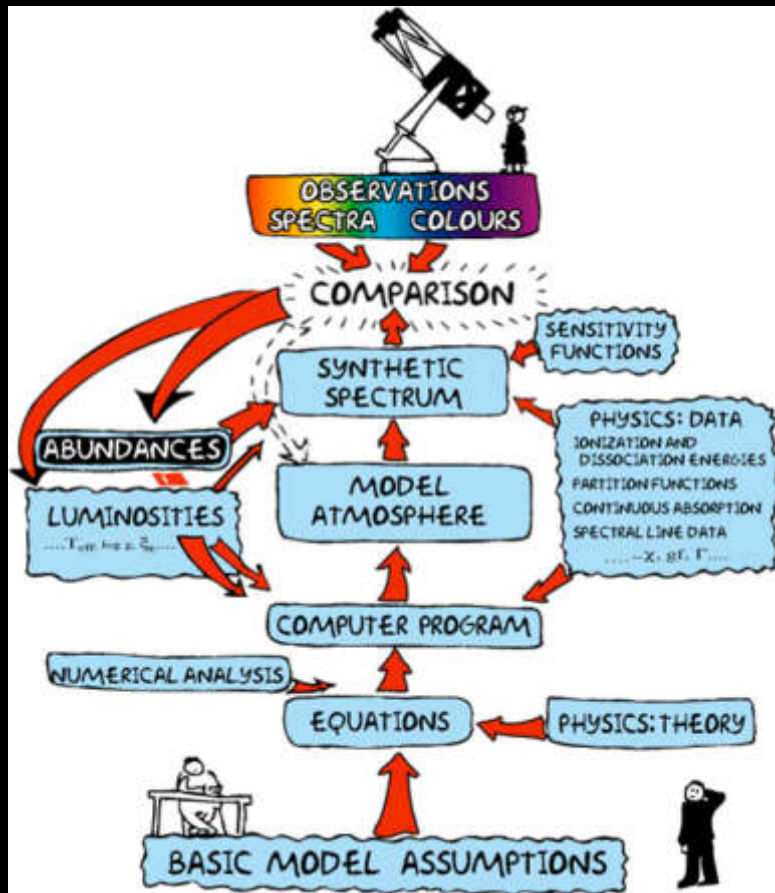

Chemical composition analysis (what I do) in one slide

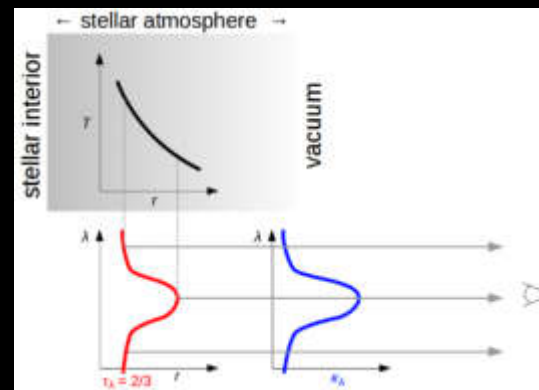

<http://webs.ucm.es/info/Astrof/invest/actividad/spectra.html>

Ryabchikova + 2005

https://en.wikipedia.org/wiki/Model_photosphere (Bengt Gustafsson)

<http://www-star.st-and.ac.uk/~pw31/education.html>

Overall metallicities can be obvious if done well

Greater interest in abundance ratios in element groups

today's focus: neutron-capture and Fe-peak elements

First: neutron-capture elements

usually includes all elements with $Z > 30$

H																	He						
Li	Be											B	C	N	O	F	Ne						
Na	Mg											Al	Si	P	S	Cl	Ar						
K	Ca	Sc	Ti	V	Cr	Mn	Fe	Co	Ni	Cu	Zn	Ga	Ge	As	Se	Br	Kr						
Rb	Sr	Y	Zr	Nb	Mo	Tc	Ru	Rh	Pd	Ag	Cd	In	Sn	Sb	Te	I	Xe						
Cs	Ba			Hf	Ta	W	Re	Os	Ir	Pt	Au	Hg	Tl	Pb	Bi	Po	At	Rn					
Fr	Ra			Rf	Db	Sg	Bh	Hs	Mt	Uun	Uuu	Uub											

The basic neutron-capture (n-capture) paths

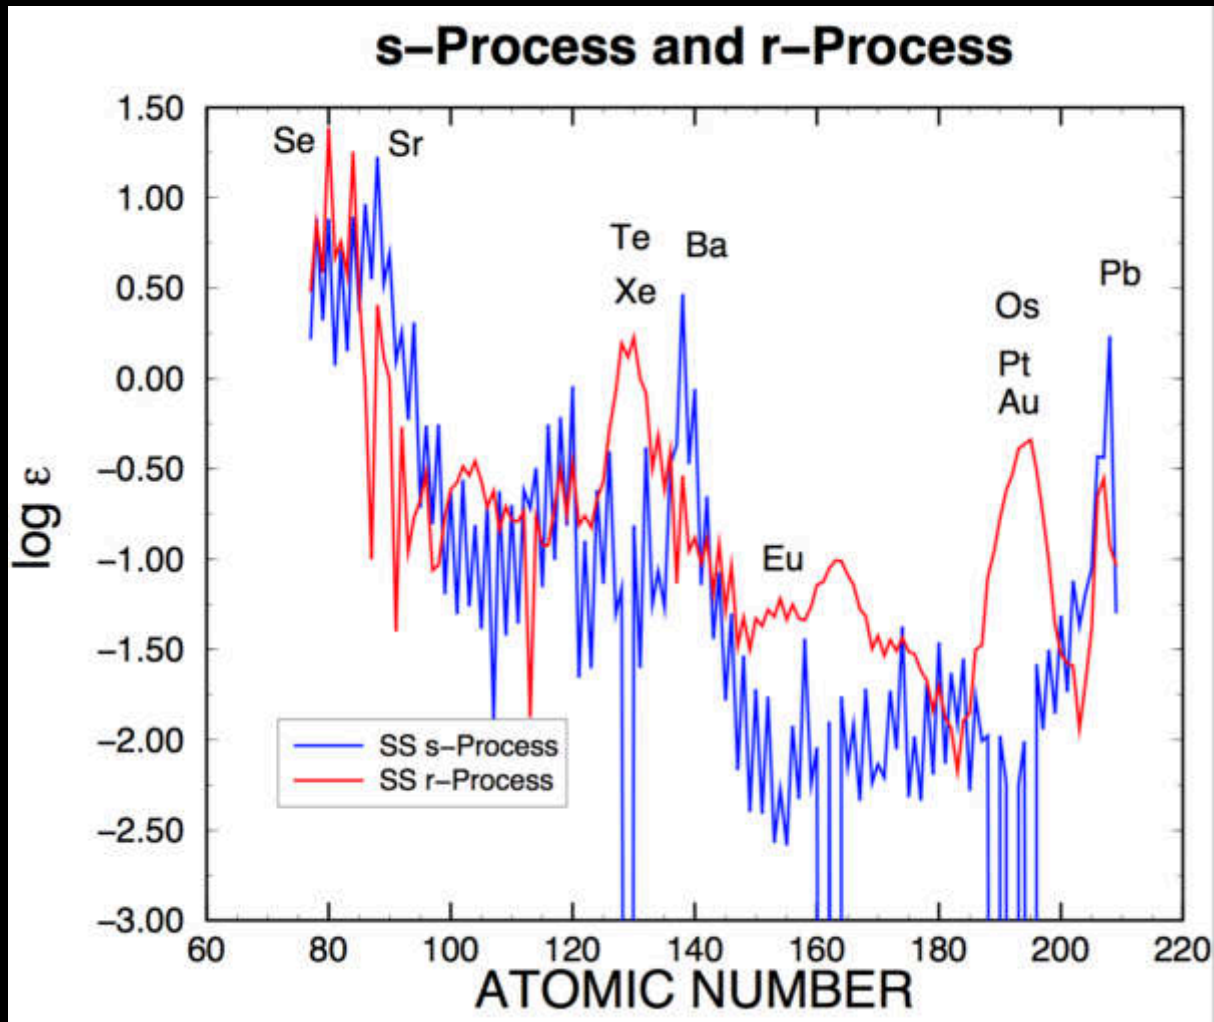

- *these elements can't be made in standard charged-particle fusion:*
 - *Coulomb barriers; endothermic reactions*
- s-process: β -decays occur between successive n-captures
- r-process: rapid, short-lived neutron blast overwhelms β -decay rates
- *r- or s-process element: **solar-system** dominance by r- or s- production*

illustrating the *r*-process pathway

here is the solar system *r*- and *s*- breakdown

these two processes each contributed about 50% of solar n-capture abundances

metal-poor stars with *gross* excesses of r-process elements are now well known

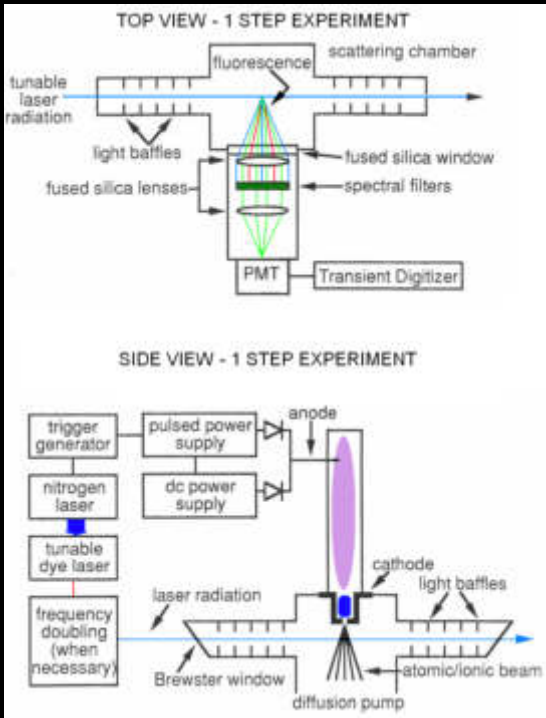

abundances of r-process-rich stars are near-perfect solar system *r*-process matches

Sneden et al. 2003

WHY are there so many elements with such good error bars?

(a) bigger telescopes; (b) better instruments; (c) [somewhat] better analytical methods; and **(d) a quiet revolution in laboratory atomic physics**

Wisconsin lab atomic
physics studies have
made major
contributions to
stellar spectroscopy

Liège, NIST, and
others

Lots of *r*-rich stars are now known ... here are some highlights

- the overall pattern is boring! Yawn?
- neutron-capture elements: “always” detected???
- Th & U abundances: reliable cosmochronometry?
- LEPP (Lighter Element Primary Process)
- lanthanide-poor but still *r*-process?
- what are the *r*-process statistics at low metallicity?
- time only to mention dwarf spheroidal *n*-capture elements

Mozart: Così fan Tutte ???

very *r*-rich stars have the
same 2nd and 3rd peak
relative abundances

upper panel:
13 *r*-II abundance
distributions and the
scaled solar *r*-process
distribution

Lower panel: mean
differences with respect
to the solar *r*-process

How metal-poor do you need to go before there are no neutron-capture elements?

see this paper for details, but simply:

if the spectra are good enough, the presence of Sr and/or Ba “always” can be detected in VERY metal-poor stars

uranium detection: vital for nuclear cosmochronometry

Hill et al. 2002

Too bad! This is a crowded spectral region with many contaminants that must be adjusted to make sense of the spectrum

Also this is in the near-UV spectral region, where stellar fluxes and spectrograph efficiencies are weaker than at longer wavelengths

This line may be the only U II transition strong enough for analysis ???

Radioactive cosmochronometry is *not* complex for metal-poor stars

Galactic chemical evolution effects do not matter for radioactive elements Th and U “frozen” into *metal-poor stars born near the start of the Galaxy*.

Daughter product Pb is also a direct *n*-capture synthesis product; it is a complex mess!

some uranium detections and meaningful limits

First detection:

CS 31082-001

(Hill et al. 2002)

The single U II line:

it is weak!

it is blended!

only with weak CN!

Frebel et al. 2007

Hill et al. 2017

Cowan et al 2002

Placco et al. 2017

LEPP: Lighter Element Primary Process

invented by Travaglio et al. 2004 to “*explain*” the scatter of 1st peak elements with respect to 2nd & 3rd peak ones

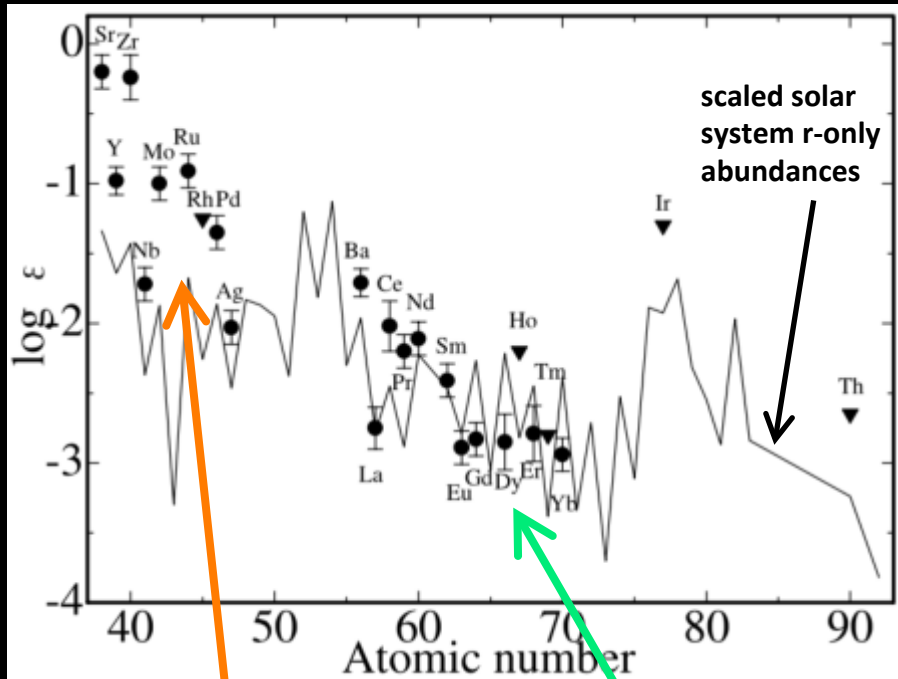

- “weak” *s*-process?
- explosive He-burning?
- *i*-process *n*-capture?
- neutrino-driven wind?

LEPP probably is a cover for a number of different nucleosynthesis mechanisms

a rare but important low metallicity class identified by close analysis of two well-known giants

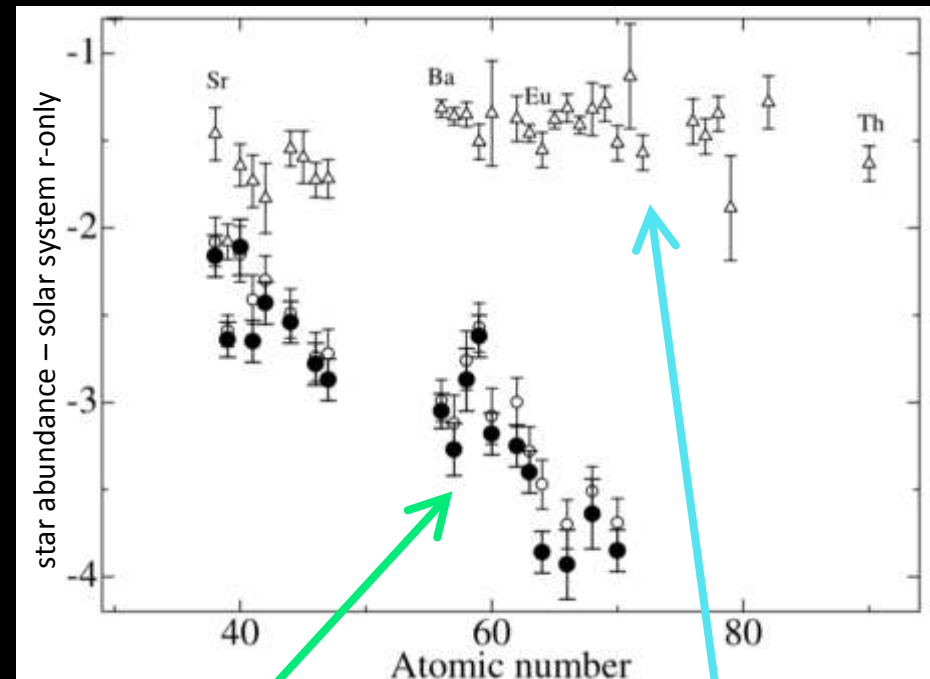

HD 88609

lots of light n-capture elements compared to heavier ones

but a reasonable match to the solar-system r-process pattern

HD 88609 & HD 122563

but the r-process is weak and dying in HD 88609 and HD 122563

CS 31082-001 (r-rich) is good match to solar system r-only abundances

The hunt to better understand the r-process: the *R*-Process Alliance (RPA)

- combines observations, theory and modeling, and experiments
- investigates different aspects of the r-process
- first goal: find the true halo distribution of r-process abundances
- want *approximate* totals to be:
 - 100 *r*-II stars: $[\text{Eu}/\text{Fe}] \geq +0.7$
 - 500 *r*-I stars: $+0.3 < [\text{Eu}/\text{Fe}] < +0.7$
 - 100 *r*-limited stars: $[\text{Eu}/\text{Fe}] \leq +0.3$
- these totals can facilitate real statistics for the first time
- can potentially lead to more U detections
- can try to understand the 1st peak abundance distributions
- can look for “imperfections” in the *r*-II abundance sets

RPA low S/N, high resolution snapshot spectra can easily find r-II stars

RPA so far: Eu abundances in 595 stars

72 r -II stars

232 r -I stars

(ignore the color shading;
it is meaningless for our
purposes)

RPA results so far: information for nuclear astro

Holmbeck+ 2020

A simple 1st conclusion: the correlations deteriorate for r-limited stars; the r-process simply has not created all the n-capture elements in these cases

Finally, don't forget this simple, crucial Eu scatter

the 2-dex $[Eu/Fe]$ spread is now confirmed with large samples

the lack of points for $[Fe/H] < -3.4$ is probably just a detection issue

note: relatively few stars with $[Eu/Fe] < -0.3$

Cowan+ 2021; Hansen+ 2018, Sakari+ 2018 are the orange points

We have no time to talk about dwarf spheroidals and the r-process

Several giants in dSph Reticulum II have large Eu overabundances

Ji et al. 2016

Brauer et al. 2019

And lots of s-process-rich stars are known

- carbon-enhanced metal-poor (CEMP) stars: many types
- CEMP-s: s-process enriched (lots of Ba, La, Pb)
- most (all) are binaries, with donor star a white dwarf
- s-process means we can model the nuclear burning
- LOTS of modeling knobs to turn
- actually have detected Bi ($Z = 83$); last stable element
- sorry, no time to discuss the other CEMP subtypes

s-process-rich stars: lead spectra, abundances

Aoki+ 2002

$[Pb/Fe] = +1.9$

$[Ba/Eu] = +0.5$

$[Pb/Fe] = +2.9$

$[Ba/Eu] = +0.8$

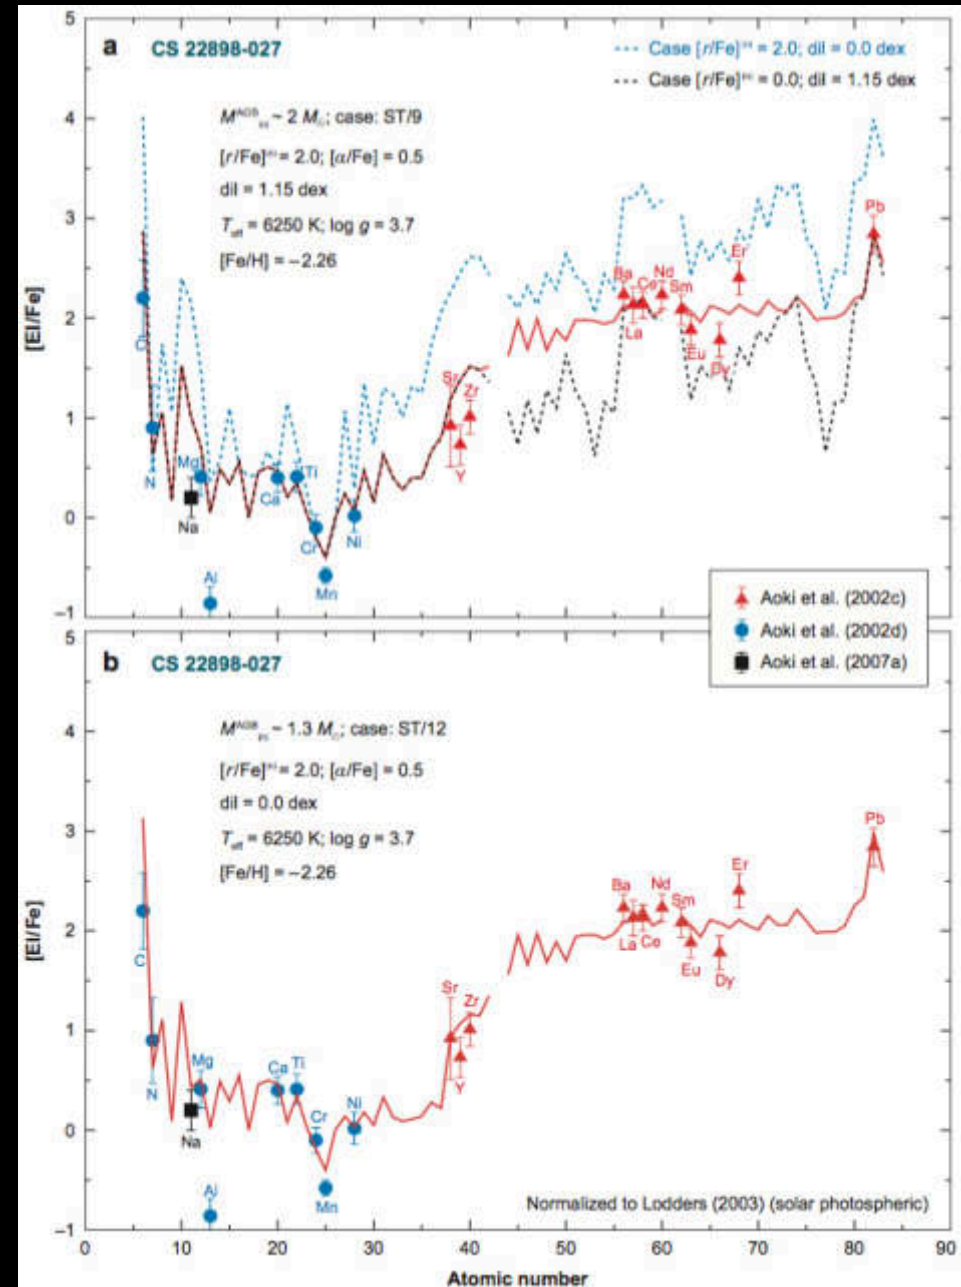

messy syntheses, but do-able

these abundance ratios are typical
in low metallicity s-rich stars

almost more parameters than abundance points

- dilution factor
- donor stellar mass
- ^{13}C envelope pocket size
- metallicity
- r-process addition?
- ratio of light/heavy elements
- CNO abundances
- etc., etc., ...

But the takeaway is simple: rational choices of well understood parameters can lead to solid abundance matches

The Fe-group elements

most abundant elements after H, He, C, N, O;
easily accessible spectroscopically (but ...);
many UV-optical lines in *various* metallicity stars

H																	He
Li	Be											B	C	N	O	F	Ne
Na	Mg											Al	Si	P	S	Cl	Ar
K	Ca	Sc	Ti	V	Cr	Mn	Fe	Co	Ni	Cu	Zn	Ga	Ge	As	Se	Br	Kr
Rb	Sr	Y	Zr	Nb	Mo	Tc	Ru	Rh	Pd	Ag	Cd	In	Sn	Sb	Te	I	Xe
Cs	Ba		Hf	Ta	W	Re	Os	Ir	Pt	Au	Hg	Tl	Pb	Bi	Po	At	Rn
Fr	Ra		Rf	Db	Sg	Bh	Hs	Mt	Uun	Uuu	Uub						
			La	Ce	Pr	Nd	Pm	Sm	Eu	Gd	Tb	Dy	Ho	Er	Tm	Yb	Lu
			Ac	Th	Pa	U	Np	Pu	Am	Cm	Bk	Cf	Es	Fm	Md	No	Lr

The Fe-group in metal-poor stars?

Aren't their abundances well known?

In short: NO!

Their abundances can be predicted quantitatively!

Signs that the usual observational results are inadequate

Major recent advances in lab atomic data of useful
transitions

The observable spectroscopic wavelength window has
greatly increased

theoretical high-mass star models generate abundances that can be compared to observed trends

those predictions clash with past claims of non-solar abundance ratios at low metallicity

$[\text{Cr}/\text{Fe}]$, $[\text{Mn}/\text{Fe}]$, $[\text{Cu}/\text{Fe}]$
are very low when
 $[Fe/H] < -2.5$

$[\text{Co}/\text{Fe}]$ is very high

McWilliam 1997, but
mostly based on
McWilliam, Preston,
Snedden, & Searle 1995

But massive star
element synthesis
models cannot
reproduce most of these
observed abundances!

Surveys with better
spectra have always
confirmed these trends

McWilliam+95 led to other surveys with better spectra

Cayrel et al. 2004

the “First Stars” survey refined the quantitative answers but the qualitative trends stayed the same

Importantly, the star-to-star scatter was decreased from McWilliam’s study, suggesting efficient mixing of early Galaxy nucleosynthetic Fe-group products

And the “spectroscopy secret” that is not obvious here is *how few* transitions of several elements were used for these abundances

theoretical predictions cannot reproduce these trends

But something was clearly amiss:
neutral and ionized
Cr transitions gave
different answers

Kobayashi et al. 2006

same theory, different observed
species of an element

example: at $[Fe/H] = -3$
 $[Cr/Fe] \approx -0.4$ from neutral lines
 $[Cr/Fe] \approx 0.0$ from ionized lines

*which abundance is right?
or maybe neither of them?!*

BIG issue: one must use ionized species for fundamental abundances in low metallicity stars

The “Saha” ionization balance

Snedden+2016

ions dominate Saha balances for Fe-group elements in warm metal-poor stars
The neutral species are mostly trace fractions →
big corrections from neutral number densities to elemental abundances

remember the American philosopher-criminal Willie Sutton

Sutton's Law: A famous apocryphal story is that Sutton was asked why he robbed banks. Allegedly he replied:

**"Because that's where
the money is"**

ionized-species lines are mostly in the UV

***Sounds easy: explore near-UV and
especially UV spectral regions***

***This means targeting warm main
sequence stars, not red giants***

a very quick summary of a “survey” of HST/STIS data on very metal-poor stars

open circles = neutral species
filled circles = ionized species

- 1) large overabundances of Sc, Ti, V
- 2) no Cr deficiency
- 3) Co overabundance *only* from Co I

Correlated Sc-Ti exists in large surveys, but have not been much noticed

final “proof” that Ti is
NOT an alpha element

The correlation of Ti with V is also clear, but it is absent with heavier Fe-group elements

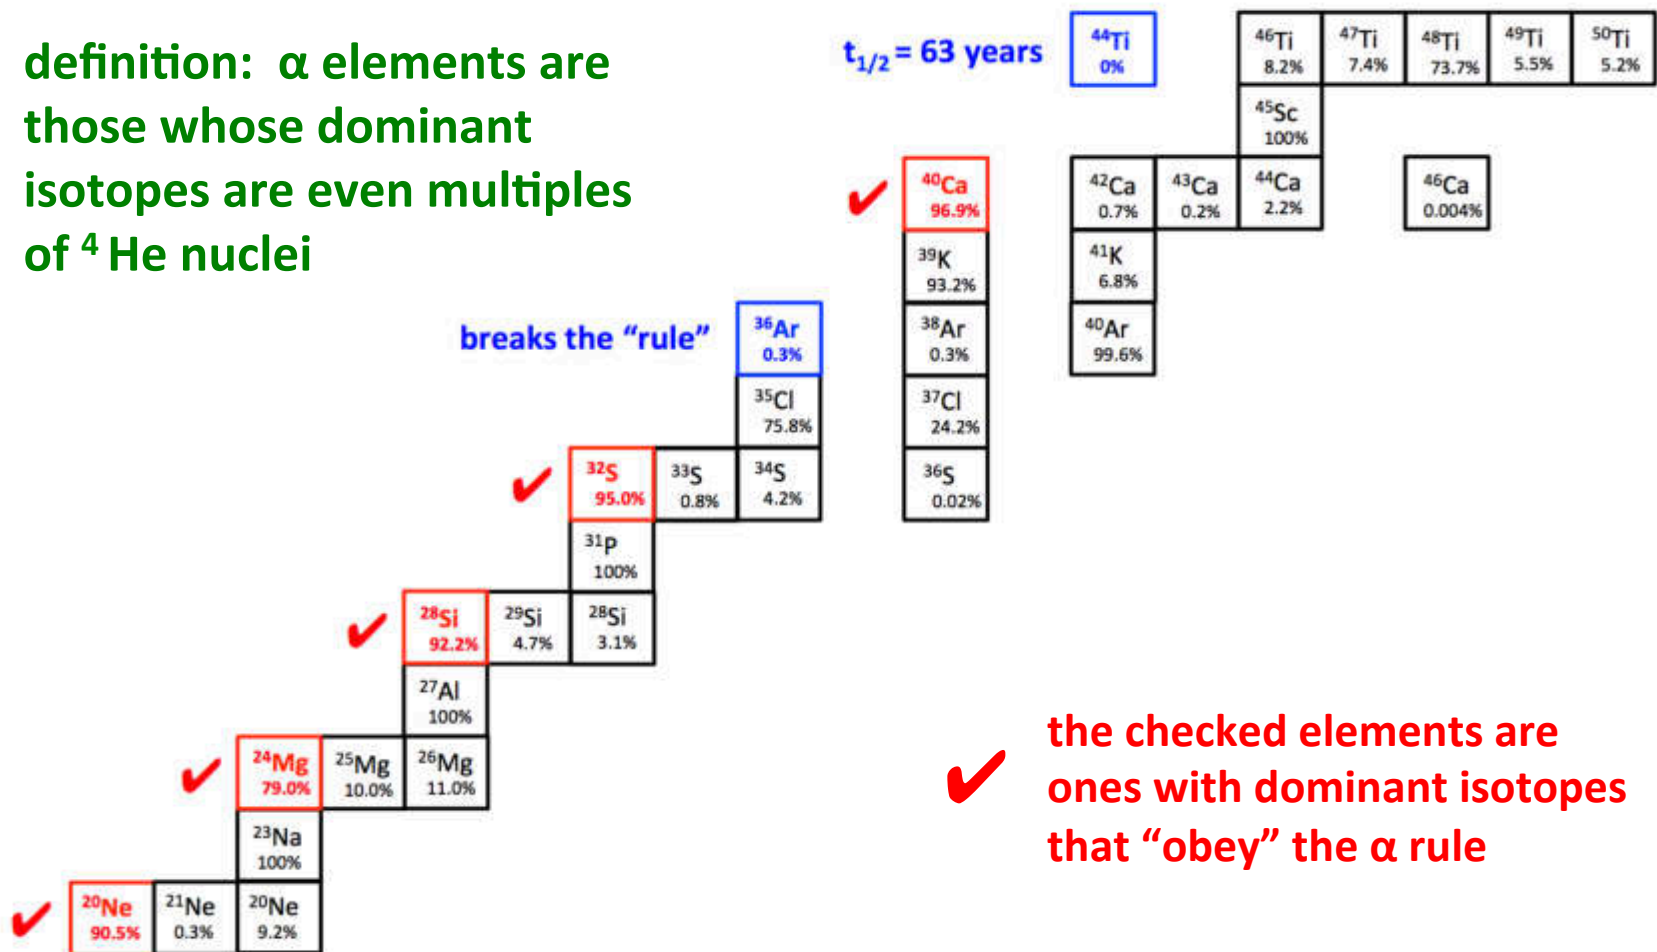

The 45° line is arbitrarily shifted to go through the mean of our 4 stars

and no obvious correlation of [Sc,Ti,V/Fe] with [Cr/Fe], [Mn/Fe], [Co/Fe], ...

For the last time ... Ti is NOT an “alpha” element

definition: α elements are those whose dominant isotopes are even multiples of ^4He nuclei

(we start with Ne ($Z=10$, $N=20$) because lighter potential α elements (C and O) also are involved in hydrogen burning, which can significantly alter their abundances)

Where is the Fe-group synthesized in massive stars?

<https://socratic.org/questions/how-is-most-of-a-star-s-total-life-spent>

Probable synthesis site for:

Si, S, Ar – oxygen fusion

Ca, Mn – “incomplete Si fusion”

Ti, Fe, Co, Ni, (Cu) – Si fusion

V, Cr, Zn – Si fusion with $Y_e > 0.5$

Sc – “inner layers with $Y_e > 0.5$ ”

see Curtis et al. 2019

Y_e = proton/nucleon ratio ... strongly affected during the explosion by neutrino and anti-neutrino captures on protons and neutrons

But wait a minute: this is not my problem!

Fe-group summary

for the first time Fe abundances in metal-poor stars are being derived from (a) enough lines, and (b) with the right (ionized) species

We do not believe past claims of large [Co/Fe] abundances at low metallicity

Sc, Ti, and V ARE correlated in this small sample, so:

For the near future: a large sample because the nucleosynthesis theories must be really tested

But nuclear astro people need us to “certify” the lighter elements at low metallicity ... back to work

a challenge from two decades ago ... just as relevant today

“So, even if the study of these surface layers appears rather boring to many of the astrophysicists, it cannot be neglected. As we have shown, even the most fundamental parameters of the most basic representation of stellar atmospheres suffer from significant uncertainties. The theoretical and observational tools needed to solve these problems are, to a large extent, available

It is therefore mostly a matter of will: there is still a lot to be done in the study of stellar atmospheres, what is needed is researchers who wish to tackle these problems.”

Pierre Magain, 1995, in “Stellar Evolution: What Should be Done”, Proc. 32nd Liège Int. Astrophysical Colloq, ed. A. Noels, D. Fraipont-Caro, M. Gabriel, N. Grevesse, and P. Demarque. Liege: Universite de Liege, Institut d'Astrophysique, 1995., p.139
